Received 3 October 2012; revised 25 February 2013; accepted 27 February 2013; published 11 April 2013.

This paper reports the metrics-based results of the $D_{st}$ index part of the 2008–2009 GEM Metrics Challenge. The 2008–2009 GEM Metrics Challenge asked modelers to submit results for four geomagnetic storm events and five different types of observations that can be modeled by statistical, climatological or physics-based models of the magnetosphere-ionosphere system. We present the results of 30 model settings that were run at the Community Coordinated Modeling Center and at the institutions of various modelers for these events. To measure the performance of each of the models against the observations, we use comparisons of 1 hour averaged model data with the $D_{st}$ index issued by the World Data Center for Geomagnetism, Kyoto, Japan, and direct comparison of 1 minute model data with the 1 minute $D_{st}$ index calculated by the United States Geological Survey. The latter index can be used to calculate spectral variability of model outputs in comparison to the index. We find that model rankings vary widely by skill score used. None of the models consistently perform best for all events. We find that empirical models perform well in general. Magnetohydrodynamics-based models of the global magnetosphere with inner magnetosphere physics (ring current model) included and stand-alone ring current models with properly defined boundary conditions perform well and are able to match or surpass results from empirical models. Unlike in similar studies, the statistical models used in this study found their challenge in the weakest events rather than the strongest events.

1. Introduction

As an increasing number of applications specify and predict space weather conditions, it becomes more important to quantitatively assess the performance of the underlying statistical and physics-based models. With quantifiable metrics, users of space weather modeling products will be able to better understand the strengths and weaknesses of each modeling approach and select the approach best suited for their application. In addition to serving the user, modelers gain insight into how different modeling parameters influence the performance of a given model and how different versions of a model are improving over time.

A metrics challenge for state-of-the-art global magnetospheric space weather models has been discussed for years in the Geospace Environment Modeling (GEM) community. The GEM Global Geospace Circulation Modeling (GGCM) Metrics and Validation Focus Group organized a modeling challenge to focus on the dynamics of the inner magnetosphere and ground magnetic field perturbations. The 2008–2009 challenge was defined at the 2008 GEM workshop in Midway, Utah, and was broadly announced in September 2008. Model result submissions were accepted through the Community Coordinated Modeling Center.
(CCMC) and submissions received through 31 March 2011 are included in this paper. Besides the online submission system, an online model comparison tool is available on the CCMC Web site to compare existing submissions to observations.

[4] This study is a collaborative effort by a large group of modelers and follows the first studies in this GEM 2008 series [Pulkkinen et al., 2010; Rastätter et al., 2011].

[5] The focus of this study is the widely used geomagnetic activity index $D_{st}$, which is derived from perturbations of the horizontal component $B_H$ of the geomagnetic field at mid-latitude stations. In this study, we use the index from two sources: the hourly index as issued by the World Data Center (WDC) of Geomagnetism at the University of Kyoto, Japan and the 1 minute index now issued by the United States Geological Survey (USGS, Gannon and Love [2011]).

[6] This 2008–2009 Challenge follows a series of earlier GEM Challenges [Lyons, 1998; Birn et al. 2001; Raeder and Maynard, 2001], but extends the focus from ionospheric convection events and isolated substorms to geomagnetic storms and observations on the ground and in geosynchronous orbit. This study is based on four events that contain a large range of geomagnetic states including three storms of various strength and one interval with an isolated substorm. The primary goals of this challenge are to evaluate differences between the available modeling approaches, study effects of model couplings and uncover the influence of model resolution. This challenge is the first in a series of challenges that can be used by anyone to track the performance measures as models improve. The ongoing collaboration between modelers and data analysts will also encourage collaboration between modelers and data analysts.

[7] The detailed analysis of the models’ performance to calculate the $D_{st}$ index is a first step in assessing the models’ ability to track geomagnetic variations on the longer 1 hour time scale as well as on the short 1 minute time scale. In the future, we are planning to extend the analysis of models’ ability to predict geomagnetic variations on the regional scale (auroral zone, sub-auroral zone and low latitudes) as is permitted by the design of the models.

[8] The overall performance of the submitted model setups and improved techniques developed both by modelers and the CCMC to obtain $D_{st}$ (and the magnetic perturbation at any station location) from model outputs. A central tool used in the analysis is the metrics evaluation tool that is available online at CCMC. All time series plots and skill scores in this paper have been generated using the online tool. This tool will continue to be upgraded as the variety of metrics challenges grow and the time scales and type of parameters analyzed change.

## 2. Setup of the Challenge

[9] Four geospace events were selected. Two events represent highly disturbed times: event 1 from 29 Oct 2003 6:00 to 30 Oct 2003 6:00 UT, known as part of the “Halloween storm” and event 2 from 14 Dec 2006 11:30 UT to 16 Dec 2006 0:00 UT, known as the “AGU storm”. The other two events represent quieter times: event 3 from 31 Aug 2001 0:00 UT to 01 Sep 2001 0:00 UT and event 4 from 31 Aug 2005 9:30 UT to 01 Sep 2005 12:00 UT. All events with their start and end dates and times, minimum $D_{st}$, and maximum $K_p$ index values are listed in Table 1.

[10] For each of the events, the solar wind magnetic field and plasma parameters obtained by the MAG and SWEPAM instruments on the Advanced Composition Explorer (ACE) satellite are shown in Figure 1. All events were covered by the ACE measurements except event 1, the “Halloween storm”, for which plasma velocity data could be reconstructed only with low time resolution [Skoug et al., 2004]. Plasma density data were constructed from the Plasma Wave Instrument on the Geotail satellite. Events 1 and 2 are large CME-related storms whereas events 3 and 4 are in less active periods.

[11] The $D_{st}$ index measures general geomagnetic activity and the strength of the inner magnetospheric currents. Currents that create a magnetic perturbation on the ground are located in the ionosphere and the near-Earth magnetosphere and consist mainly of the ring current. When calculated from magnetospheric and ionospheric current systems, the $D_{st}$ index is approximated by the magnetic perturbation at the center of the Earth. All current systems in the ionosphere and magnetosphere [Yu et al., 2010] are equally important.

## 3. Models Used

[12] Models used for this challenge fall into four groups that reflect the different physics and numerical approaches taken by the models.

### 3.1. Three-Dimensional Magnetosphere Models

[13] These models are three-dimensional (3-D) magnetohydrodynamic (MHD) models of the magnetosphere that are coupled to an ionosphere electrodynamics solver. Models of this category are the Space Weather Modeling Framework (SWMF) [Tóth et al. 2005], the Open Geospace General Circulation Model (OpenGGCM) [Raeder et al., 2001a], and the Coupled Magnetosphere-Ionosphere-Thermosphere (CMIT) model, also referred to by the magnetospheric Lyon-Fedder-Mobarry (LFM) component [Lyon et al., 2004; Wiltberger et al., 2004; Merkin and Lyon, 2010]. These models are run on clusters of computers and require large amounts of computing time and storage space for output.
Figure 1. Solar wind bulk plasma and magnetic field observations for the four events listed in Table 1.
The parameter sets for these models are identical to the previously reported runs [Rastätter et al., 2011] (the IDs are listed in Table 1). The $D_e$ index is calculated from two contributions:

**[a]** Magnetosphere currents: Electric currents from the magnetosphere outside of the “current pickup radius” of the magnetosphere model are used to calculate the magnetic perturbation $\delta B$ by using the Biot-Savart formula.

$$\delta B = \frac{\mu_0}{4\pi} \sum \frac{J \times R}{R^4} dV$$

with $\mathbf{R}$ being the radius vector to a grid cell with current density $\mathbf{J}$ and volume $dV$. The “current pickup radius” is the radial distance from the Earth’s center at which electric currents calculated by the magnetospheric model component are sampled to obtain magnetic field-aligned currents (FAC). For SWMF and OpenGGCM, this radius is $3R_E$, one or two grid cell layers away from the inner boundary (at $2.5R_E$). For LFM, the inner boundary of the magnetosphere grid (cell centers) is located at about $2.2R_E$ and currents that flow into the ionosphere are picked up from near that boundary. The calculation of currents in the LFM magnetosphere is done in a post-processing step using single precision magnetic field data stored in the LFM output. This results in significant errors near the inner boundary due to the strong dipole field gradient. As a consequence, we exclude currents calculated from within the first four grid layers, roughly $3.5R_E$. This is different from the calculations done with the OpenGGCM and SWMF models, which only show significant errors within the first grid layer adjacent to the inner boundary. Only volume elements (magnetosphere grid cells) $dV$ that are centered at positions $\mathbf{R} = [x, y, z]$ beyond this “inner boundary” radius from the Earth’s center are considered.

**[b]** Ionospheric currents: Height-integrated currents in the ionosphere (assumed to be centered at an altitude of 110 kilometers [Yu and Ridley, 2008]) that close the field-aligned currents are considered using equation 1. For $dV$ in equation 1, we here use 2-D surface elements instead of 3-D volume elements. We employ the currents in cartesian coordinates $(J_x, J_y, J_z)$ reported by the ionospheric electrodynamic solvers on the respective mode’s grid for a full Biot-Savart summation. Latitudinal resolution ranges between 0.5 degrees (OpenGGCM), 1.4 degrees (SWMF) and 2 degrees (LFM). Longitudinal resolution is 2 degrees for all models.

**[c]** Field-aligned currents: In this study, the contribution of FAC to $D_e$ is exactly zero due to the fact that $D_e$ is being calculated as the north (axial) component of the magnetic perturbation at the Earth’s center. Currents that are picked up from the magnetosphere and mapped as field-aligned currents along dipolar field lines are purely poloidal in SM spherical coordinates $(r, \theta, \phi)$ since the dipole field has no $\phi$ component. Any contribution to the magnetic perturbation at the Earth’s center is proportional to the cross product of two poloidal vectors (the position $\mathbf{r}$ and current element $\mathbf{J}$ that have components in the $r$ and $\theta$ direction only) and thus is purely toroidal (i.e., in the $\phi$ direction in spherical coordinates). Since the polar axis is poloidal (radial direction for $\theta = 0$), the sum of toroidal contributions projected along the axis remains zero regardless of the spatial distribution of the FAC.

**[17]** Using the contributions from magnetospheric and ionospheric currents, $D_e$ is approximated by the North-South component of the perturbation magnetic field $B_Z$ in SM coordinates at the Earth’s center location. The magnetic perturbation is obtained by transforming contributions from the magnetosphere to SM coordinates and adding the contribution from the ionospheric currents that already comes in SM coordinates from each of the models.

**[18]** At CCMC, the magnetohydrodynamic (MHD) models of the global magnetosphere, SWMF, OpenGGCM and CMIT are run routinely for Runs-on-Request and thus were run for the four events.

### 3.1.1. SWMF

**[19]** SWMF is run here as a combination of the magnetosphere MHD component (SWMF/GM/BATSRUS) coupled to the Ridley Ionosphere Model (SWMF/IE/RIM) electrodynamic solver [Tóth et al. 2005]. Some runs include an inner magnetospheric component: the Rice Convexion Model (SWMF/IM/RCM2) or the Comprehensive Ring Current Model (SWMF/MCRCM). We performed four runs for each event with SWMF, spanning the setup for real-time simulation (755,000 grid cells) to higher-resolutions Run-on-Request grids (two and three million grid cells, respectively). One run was performed without a ring current model (4_SWMF), two others (5_SWMF, 8_SWMF) were run with the Rice Convexion Model (RCM), and one setting (7_SWMF) was run with the Comprehensive Ring Current Model (CRCM), which was recently developed at NASA GSFC [Buzulukova et al., 2010]. The CRCM model is coupled into SWMF in a similar manner as the RCM model [DeZeeuw et al. 2004]. Both coupled ring current models require the same information (magnetic fields, plasma density and temperature) from the magnetosphere MHD model and return the same modifications (plasma pressure) back to the MHD model. SWMF runs with one million grid cells at 0.25 $R_E$ resolution (8_SWMF) can be executed in real time on a cluster with 64 processors. Larger grids used in 4_SWMF, 5_SWMF, and 7_SWMF take proportionally longer. Finer resolution (i.e., 0.125 $R_E$ used in 5_SWMF) takes twice as much time in explicit time stepping. Run 7_SWMF took 2.7 times longer than real time on 200 processors (or about eight times longer on 64 processors) using a serial version of CRCM. With a parallelized version of CRCM (A. Glocer, submitted paper), this run may run close to or faster than real time on 200 processors.

### 3.1.2. OpenGGCM

**[20]** The OpenGGCM magnetospheric MHD model was run with the Coupled Thermosphere-Ionosphere Model (CTIM) [Fuller-Rowell et al., 1996] and the OpenGGCM model’s ionospheric potential solver as described in Raeder et al. [2001b]. Runs performed with model version 3.1 have a fixed geomagnetic dipole orientation. Runs with model version 4.0 include an updating dipole orientation. OpenGGCM was run with a medium-resolution grid of 6.55 million cells with minimum cell size of 0.25 $R_E$ for 2_OPENGGCM and 3.88 million cells with a minimum cell size of 0.25 $R_E$ for 4_OPENGGCM. Runs of 2_OPENGGCM were two times slower than real-time on 64 processors whereas 4_OPENGGCM performed in real-time.
3.3. CMIT

[21] The Coupled Magnetosphere, Ionosphere and Thermosphere (CMIT) model [Wilberger et al., 2004] consists of the Lyon CCMC model (LFM) magnetosphere [Lyon et al., 2004], the MIX ionosphere electrodynamics solver [Merkin and Lyon, 2010] and the TIE-GCM ionosphere-thermosphere model [Richmond et al., 1992]. The CCMC employed standard settings of two model versions: LTR-2_1_1, available in 2011, for run 2_LFM-MIX with the LFM and MIX components, and LTR-2.1.5, issued in 2012, for run 2_CMIT that also includes the TIE-GCM ionosphere model to specify the ionospheric conductances. The LFM grid with 53 x 48 x 64 boxes has radial spacing of about 0.4RE in the dayside magnetosphere (within 10RE). CMIT runs execute in real-time on 24 processors.

3.2. Low-Dimensional Models of the Magnetosphere-Ionosphere

3.2.1. WINDMI

[22] This category includes a single model WINDMI.

3.3. Kinetic Ring Current Models

[24] Ring current models are run either in stand-alone mode or coupled to one of the magnetospheric models mentioned above. Models included here are the Ring Current-Atmosphere Interactions Model with Self-Consistent Magnetic Field (RAM-SCB) and the Rice Convection Model (RCM).

[25] The total energy in the ring current is converted to \( D_{\text{a}} \) using the Dessler-Parker-Sckopke relation [Dessler and Doxas, 1998; Mays et al., 2009]. \( D_{\text{a}} \) is one of the model’s outputs and is obtained from the ring current energy using the Dessler-Parker-Sckopke relation (see equation 2, which is discussed in the ring current model section below). The WINDMI model solves a set of ordinary differential equations with parameters that can be physically motivated. For this reason, WINDMI has been grouped with the 3-D magnetosphere MHD models in plots and listings of skill scores in the remainder of this paper. The model was run with a nominal parameter set as listed in Table 1 in Mays et al. [2009] and three different solar wind coupling functions. WINDMI runs very fast and takes less than a minute on a single processor to produce a day’s worth of \( D_{\text{a}} \) at a 1 minute cadence.

3.3.1. RAM-SCB

[26] Runs with the Ring-current Atmosphere interaction Model with Self-Consistent 3D magnetic (B) field (RAM-SCB) [Jordanova et al., 1994, 2010; Cheng, 1995; Zaharia et al., 2004; Yu et al., 2011] were performed in stand-alone mode using two models for the equatorial electric field (Kp-dependent Volland-Stern; Volland [1973]; Stern [1975]; Burke [2007], and the interplanetary plasma and magnetic field dependent Weimer 2000 [Weimer, 2001]). The plasma boundary conditions were specified after geosynchronous LANL satellite data, while the Tsyganenko-89 [Tsyganenko, 1989] and the SWMF models were used to specify the magnetic field conditions.

[27] Two runs of RAM-SCB (4_RAMSCB and 5_RAMSCB) were coupled to SWMF. Plasma boundary conditions and magnetic fields are provided by the BATSRUS magnetosphere model, and the electric field is provided by the RIM ionosphere electrodynamics model. For 5_RAMSCB, SWMF was also run with the Polar Wind Output Model that describes the mass loading of the magnetosphere from the ionosphere [Welling et al., 2011]. The various runs with RAM-SCB have been described in detail in comprehensive validation studies by Welling et al. [2011] and Yu et al. [2011].

[28] In each RAM-SCB model run, the self-consistent magnetic field determination (SCB) takes most of the computer time. Without SCB (run 1_RAMSCB) the stand-alone RAM-SCB model can run up to 18 times faster than real-time. With SCB (2_RAMSCB, 3_RAMSCB), the model runs between one and five times faster than real-time. Time discretization that is mandated by the dynamics of an event affects total run time. Larger storms require smaller time steps and slow down computations considerably. The two runs coupled with SWMF (4_RAMSCB, 5_RAMSCB) require a cluster with 200 processors and run between two and four times slower than real time. Due to the computational expense and the cutting-edge development required, 4_RAMSCB and 5_RAMSCB were not run for all events. Results were submitted for illustration and benefit of the GEM community.

3.3.2. Rice Convection Model

[29] The Rice Convection Model (RCM) is a well-established and extensively used model of the plasma electrodynamics in the inner magnetosphere and its coupling to the ionosphere [Harel et al., 1981; Wolf et al., 1991; Szajkin, 2000; Toffoletto et al., 2003]. The model describes the \( \mathbf{E} \times \mathbf{B} \) and gradient-curvature drifts of an isotropic plasma on closed magnetic field lines in parts of the inner magnetosphere [Wolf, 1983]. Field-aligned currents are calculated from the magnetospheric plasma pressure gradients using the Vasyliunas equation [Vasyliunas, 1970]. The FAC determine the ionospheric potential and electric fields that are mapped back into the magnetosphere to close the computational loop. The RCM is driven by input functions that include the magnetic field, the electric potential distribution on the high-latitude boundary, the ionospheric conductance, and the influx of particles across the high-latitude boundary.

[30] The RCM was run with the Hilmer and Voigt magnetic field description [Hilmer and Voigt, 1995] and with either the Siscoe-Hill [Siscoe 1982; Hill, 1984; Burke et al. 2007] or the Weimer [Weimer, 2005] electric field models. Plasma sheet boundary conditions were specified by the Tsyganenko and Mukai [Tsyganenko and Mukai, 2003] model, by plasma transport conditions specified by Borovsky et al. [1998], or by the Magnetosphere Specification Model.
The coupling function and decay rate then yield the strength of the ring current $D_a^*$ via:

$$\frac{d}{dt} D_a^* = F(E_y) - \frac{D_a^*}{\tau}$$  \hspace{1cm} (7)$$

The iterative method starts from an initial $D_a^*$ value that may be obtained as a quiet time driver multiplied by the inverse of the decay rate $D_a^* = F(E_y(t_0))/\tau$ at a time $t_0$ several hours before the time interval of interest. The numerical formulation then uses solar wind data available every minute. $D_a$ is computed from $D_a^*$ using equation 3.

### 3.4.3. NARMAX

The NARMAX algorithm [Billings et al., 1989] is an advanced system identification technique, similar to neural networks. A NARMAX model is able to represent a wide class of linear and non-linear systems with physically interpretable parameters [Leonarditis and Billings, 1985a, 1985b]. The output $y(t)$ of the model at time $t$ is a polynomial function $F$ of the previous values of inputs $u$, outputs $y$, and error terms $e$ as described by equation 8.

$$y(t) = F[y(t-1), \ldots, y(t-n_y),
\begin{array}{c}
u_1(t-1), \ldots, u_1(t-n_{u1}), \\
u_2(t-1), \ldots, u_2(t-n_{u2}), \\
e(t-1), \ldots, e(t-n_e) + e(t)
\end{array}$$  \hspace{1cm} (8)$$

Index $m$ is the number of inputs to the system and $n_y, n_{u1}, \ldots, n_{u2}$ are the maximum time lags of the output and the $m$ inputs, respectively. The NARMAX algorithm was first applied to magnetosphere predictions by [Boaghe et al. 2001]. Here, a model of the $D_a$ index was derived using $v_B$ as the input. This model was shown to have a high correlation and coherency with the measured $D_a$ index. For the $D_a$ NARMAX models, the function $F$ is a quadratic polynomial, in which the monomials comprise all the possible quadratic cross-coupled combinations of past inputs, outputs and error terms. Here, the output is the $D_a$ index, and the inputs are the solar wind parameters. The NARMAX algorithm consists of three stages: model structure selection, parameter estimation and model validation. The first stage is aimed at reducing the large number of possible monomials by determining the most significant monomials using the Error Reduction Ratio (ERR) [Billings et al., 1989]. The monomials with a small ERR are deemed negligible, while the monomials with a high ERR are carried on to the second stage, the parameter estimation, where the coefficients for each of these monomials are calculated. During the last stage, the model is validated by exploiting both dynamic and statistical approaches [Billings and Voon, 1986]. More recently, Boynton et al. [2011a] also employed the NARMAX algorithm to deduce a model for the $D_a$ index using a different coupling function ($\rho^{3/2} v_B^2 B_t \sin \theta/2$) as an input. This coupling function was shown to be the best coupling function for the $D_a$ index using an ERR analysis [Boynton et al., 2011b]. The model by Boynton et al. [2011a] was shown to have a higher correlation and coherency with the measured $D_a$ than that of Boaghe et al. [2001]. A startup of 50 hours is sufficient to allow the system to reach a state.
that is independent of the initial $D_s$ values that have to be set arbitrarily (usually zero).

### 3.4.4 RiceDST

[35] The RiceDST model is a neural-network-based time prediction model. The model is driven by input time histories (10 hours) of solar wind coupling function described by the Boyle function [Boyle et al., 1997], an empirical approximation that estimates the Earth’s polar cap potential, and the solar wind dynamic pressure to predict the $D_s$ index approximately 1 hour ahead. The model can be run in real-time through inputs from an upstream solar wind monitor such as ACE [Bala and Reiff, 2012] to specify $K_p$, $D_s$, and $AE$ indices. As of 2012, the model is operational and the real-time estimates of the indices can be obtained from http://space.rice.edu/ISTP/wind.html.

### 3.4.5 RDST

[36] Space Environment Corporation developed a real-time $D_s$ estimator with robustness of the calculation in mind given that real time data streams are not assured. The RDST CALC program produces the real-time $D_s$ (RDST) value as the best possible estimate of $D_s$ whether there are four, three, two or one magnetic observatories available for the analysis. The RDST CALC program is currently deployed at Air Force Weather Agency (AWFA). The first difference of the RDST calculation from the traditional $D_s$ determination is that RDST is based on Hermanus (HER), Honolulu (HON), San Juan (SJG), and Guam (GUA) magnetic observatories. The Guam Magnetic Observatory replaces the Kyoto Magnetic Observatory for the Pacific sector to assure a robust data stream to AWFA.

The RDST algorithm also has differences from the traditional definitive calculation of $D_s$ to strive for the best estimate of the definitive $D_s$ with uncertain real-time data streams. Each station is used to make a best estimate of the definitive $D_{s\text{st}}$, then the available estimates of each station are averaged to produce the RDST value. Each single-station $D_{s\text{st}}$ estimate uses similar reduction algorithms to the traditional $D_s$ analysis. The first step is to provide a stable estimate of the Secular Variation (SV) within the horizontal component for each station, $s$, $(H_s^{\text{SV}})$. The second step is to obtain the current Solar Quiet (SQ) variation of the horizontal component with the secular variation removed $(H_s^{\text{SQ}})$. Removing these two components leaves the station's ring current deflection, $\Delta H_s$.

$$\Delta H_s = H_s - H_s^{\text{SQ}} - H_s^{\text{SV}}.$$ (9)

The standard latitudinal dependence is applied to the $\Delta H_s$ value. There is an expected Universal Time dependence in the response of a single station to the magnetospheric currents. The single station estimate of $D_s$ is obtained using a linear regression analysis for each UT hour of $\Delta H_s$ and the historic definitive $D_s$. Reduction is adjusted with a set of linear coefficients, which have a Universal Time dependence:

$$\text{RDST}_s = a_s(t) \frac{\Delta H_s}{\cos \lambda} + b_s(t)$$ (10)

where $\lambda$ is the magnetic latitude of Earth’s tilted dipole. Finally, the four, three, or two single-station estimates of $D_{s\text{st}}$ are averaged to obtain a robust real time estimate of the definitive $D_s$. RDST values are obtained at the standard 1 hour cadence.

[37] The above four groups of models all use the solar wind data (RDST; magnetometer data) as input. None of the models use the observed $D_s$ as input. The detailed model parameters are listed in Table 2.

### 4. The $D_s$ Index

[38] Analyses and skill score calculations were performed using two implementations of the $D_s$ index that measures...
the strength of the ring current and is used generally as a proxy for the intensity of geomagnetic activity.

4.1. The Kyoto $D_{st}$ Index

[39] The $D_{st}$ index is an averaged north-south perturbation of the geomagnetic field obtained by using observations at four stations ($N = 4$, $n = 1, \ldots, N$) located at magnetic mid-latitudes: Kakioka in Japan (geographic longitude = 140.18, latitude = 36.23), Honolulu in Hawaii (lon. = 201.98, lat. = 21.32), San Juan in Puerto Rico (lon. = 293.88, lat. = 18.11) and Hermanus in South Africa (lon. = 19.22, lat. = -34.40). The $D_{st}$ index is defined as a 1 hour average of magnetic disturbances (H) measured at the four stations, weighted by the cosine of the respective magnetic latitude at each station [Sugiura, 1964; Love and Gannon, 2009]:

$$D_{st} = \frac{1}{N} \sum_{n=1}^{N} H_n \cos(MLAT_n).$$

(11)

For the comparisons, we use the final index, which is published by the World Data Center for Geomagnetism in Kyoto, Japan, between 3 and 6 years after the magnetometer observations have been gathered (final data are currently available through the end of 2008). The 1 hour averaged index has been produced since 1957. The index has been modified and improved over the years (e.g., Sugiura and Hendricks [1967]; Sugiura and Kamei [1991]; Karinen and Mursula [2006]). The disturbance $H$ is obtained by subtracting the diurnal variation of the horizontal magnetic field from an average of several of the quietest days around the time of the observation. This method, however, requires a substantial amount of data before and after a measurement to determine the quiet-time baseline.

4.2. The USGS $D_{st}$ Index

[40] The United States Geological Survey (USGS) has recently developed a system to determine $D_{st}$ on a 1 minute time scale [Gannon et al., 2011; Gannon and Love, 2011]. The derivation of the baseline involves frequency domain analysis and can be performed in near-real-time as opposed to the Kyoto $D_{st}$ index that uses long-time series to determine the baseline. Thus nearly definitive $D_{st}$ values are available almost immediately using 1 year of data to determine the $S_q$-harmonics. The real-time USGS $D_{st}$ is very similar to the definitive USGS $D_{st}$ (99.5% correlation). We use definitive 1 minute USGS $D_{st}$ data for the events studied, with baseline removal based on the analysis of 23 years of nearly continuous magnetic observatory data. Since the USGS-$D_{st}$ is a 1 minute index, it allows us to better study the faster time evolution of the magnetic perturbation in the inner magnetosphere. The same time cadence can be obtained by physics-based models of the magnetosphere and ring current and the BFM $D_{st}$ specification model. It is important to note that USGS $D_{st}$ index is derived using a different normalization compared to the Kyoto $D_{st}$ to correct for the four stations’ magnetic latitudes:

$$D_{st} = \frac{1}{N} \sum_{n=1}^{N} H_n \cos(MLAT_n).$$

(12)

Love and Gannon [2009] compared Kyoto and USGS $D_{st}$ values for years from 1957 through 2007. The comparison showed that Kyoto $D_{st}$ values are on average 8.60 nT lower than the USGS $D_{st}$ values. The root-mean square difference between the indices is 11.01 nT. Several strong storm events were found to have substantial difference in terms of minimum $D_{st}$ values. While we do see a difference in the baseline between the two implementations of the $D_{st}$ index, the $D_{st}$ minima are very similar in the storms used in this study.

5. Types of Skill Scores

[41] We employed the Prediction Efficiency ($PE$) and the Log-Spectral Distance ($M_s$) as used in Rastätter et al. [2011]. In addition, we add the Correlation Coefficient ($CC$), Model Yield ($YI$) and the Timing Error ($\Delta T$) to the analysis, and we also chart the models’ performance using a combination of two scores at a time to assess the performance of classes of model runs. The skill scores used in this paper are described below:

5.1. Prediction Efficiency $PE$

[42] The $D_{st}$ values provided by the models introduced in the previous sections can be evaluated by computing a Prediction Efficiency ($PE$), defined for a discrete time series as follows:

$$PE = 1 - \frac{< (x_{mod} - x_{obs})^2 >}{\sigma_{obs}^2}$$

(13)

with $< \ldots >$ denoting the arithmetic mean, $x_{obs}$ the observation, $x_{mod}$ the modeled signal, and $\sigma_{obs}^2 = < x_{obs}^2 >$ the variance of the observed signal. The numerator is often referred to as the Mean Squared Error (MSE). $PE = 1$ indicates perfect model performance and $PE = 0$ indicates performance comparable to predicting the arithmetic mean of the observed signal. $PE$ can reach unlimited negative values.

5.2. Log-Spectral Distance $M_s$

[43] The spectral power determines the level of disturbance on different time scales that can be produced by the models in comparison to the observed level of fluctuations. The analysis of the Log-Spectral Distance evaluates the spectral distribution of fluctuations in a given spectral range. This is accomplished by computing a single number that measures the distance between the observed spectral distribution from that obtained by a model. The comparison of spectral distributions in the model outputs compared to the observations (and solar wind inputs) indicates how well a model preserves activity levels in various frequency ranges. A model would perform perfectly if the spectral distribution in the observations matched the modeled spectrum. To compute the Log-Spectral Distance, the logarithm of the ratio of the spectral power of the observed ($\langle |\tilde{x}_{obs}| \rangle$) and modeled variable ($\langle |\tilde{x}_{mod}| \rangle$)

$$m_s = \log \left[ \frac{\langle |\tilde{x}_{mod}| \rangle}{\langle |\tilde{x}_{obs}| \rangle} \right]$$

(14)
Figure 2. One minute USGS $D_{st}$ data and magnetosphere model results. Magnetosphere models listed in the first section in Table 2 are shown in color: SWMF in brown and red, OpenGGCM in blue, CMIT/LFM in purple and WINDMI in green colored traces. The panels show the individual events: (a) event 1 (29–30 Oct 2003), (b) event 2 (14–16 Dec 2006), (c) event 3 (31 Aug–1 Sep 2001) and (d) event 4 (31 Aug–1 Sep 2005).

is calculated for each frequency. The root mean square of $m_i$ over the $N$ frequencies $f$ yields the Log-Spectral Distance $M_s$:

$$M_s = \frac{1}{N} \sum_{f} m_i^2.$$  

(15)

The score $M_s$ is equal or larger than zero. $M_s = 0$ is a perfect score. To perform the spectral analysis, 2 hour length windows are selected from the 1 minute data and model results, yielding a Fourier spectrum for periods between 2 minutes ($f_1 = 1/120$ hertz) and 120 minutes ($f_2 = 1/7200$ hertz). A 75% overlap between adjacent windows is allowed. Spectra from all valid windows (those that have no missing data) are averaged to form the spectra from the observation data ($x_{obs}$) and model outputs ($x_{mod}$).

[44] The computation of spectra does not make sense for the Kyoto $D_{st}$, which is defined on an hourly basis. We can, however, use the spectral analysis for the USGS $D_{st}$ values that are available on a 1 minute scale as long as the model output time resolution is comparable.

5.3. Correlation Coefficient

[45] The Correlation Coefficient (CC) is the cross-correlation computed with zero lag:

$$CC = \frac{\langle x_{obs} x_{mod} \rangle}{\sigma_{obs} \sigma_{mod}}.$$  

(16)

A CC of 1 is perfect correlation and –1 is perfect anti-correlation (model values with same shape but with opposite sign compared to observations). Both $PE$ and $CC$ require the observation signal in the denominator to have nonzero variances ($\sigma_{obs}^2 > 0$). To obtain a finite CC, the modeled signal also needs to have a non-zero variance ($\sigma_{mod}^2 > 0$). Quiet events with low variance in the observation signal may amplify modeling errors in these scores.

5.4. Modeling Yield

[46] The Modeling Yield $YI$ compares the largest change seen in the modeled index value versus the observed index. This skill score is suitable for a quantity that starts from a constant baseline (e.g., zero) and for events that are characterized by a single peak or minimum.

$$YI = \frac{\max(x_{mod}) - \min(x_{obs})}{\max(x_{obs}) - \min(x_{obs})}. $$  

(17)

A modeling Yield of 1 is an ideal score. Yields near 1 may indicate a good model performance, but only if they are accompanied by good values of the Correlation Coefficient $CC$.

5.5. Timing Error

[47] The Timing Error $\Delta T$ applies to events where a time series shows distinct extreme values (minima in the case of $D_{st}$). $\Delta T$ is the time difference between the time of the observed minimum and the time of the modeled minimum of $D_{st}$. A $\Delta T$ of zero hours is ideal.

[48] Many geomagnetic storms show a single minimum followed by a monotonic recovery phase. Often, however, geomagnetic storms feature multiple onsets of activity.
In fact, among the events of this study, we find two distinct minima in event 1 and a long period of near-minimum $\text{D}_{\text{st}}$ values during event 2 that can be considered as having two minima as well. In the analysis, we will consider two parts of the time series for events 1 and 2 to better analyze model performance with respect to $\Delta T$.

6. Results

[49] Using USGS data, $CC$, $PE$ and $M_i$ were derived by interpolating model outputs written on longer cadences to the 1 minute cadence of the USGS data. We calculate the Timing Error and the Yield using 1 hour Kyoto $\text{D}_{\text{st}}$ observations and also calculate $CC$ and $PE$ with Kyoto data. Model results with a smaller time resolution than 1 hour were averaged to the 1 hour time cadence of the Kyoto $\text{D}_{\text{st}}$ to perform these comparisons.

[50] Global magnetospheric models were run to provide $\text{D}_{\text{st}}$ as a snapshot of the effects of the global current system at a 1 minute cadence (7_SWMF and 8_SWMF generate disturbances at a 5 second cadence that were subsampled at 1 minute intervals). Magnetosphere MHD models other than 7_SWMF and 8_SWMF use a post-processing step developed at CCMC to compute $\text{D}_{\text{st}}$ from magnetospheric and ionospheric currents contained in model outputs written every minute. Ring Current models (RCM, RAM-SCB) provide outputs every 5 minutes. The $\text{D}_{\text{st}}$ specification models output 1 hour $\text{D}_{\text{st}}$ values, except for the BFM formula. BFM produces output at the data rate (ACE-L2, interpolated to a 1 minute cadence) that is sufficient for comparison with USGS 1 minute $\text{D}_{\text{st}}$ data to obtain spectral information.

[51] Figures 2, 3 and 4 show the time series data used for the study. Figure 2 shows the USGS $\text{D}_{\text{st}}$ data values and results obtained from the magnetosphere models (SWMF, OpenGGCM, CMIT, LFM-MIX) and WINDMI. Figure 3 shows the USGS $\text{D}_{\text{st}}$ data values and results obtained from the ring current models RCM and RAM-SCB. Figure 4 shows the Kyoto $\text{D}_{\text{st}}$ data values and outputs from the specification models (IRF, BFM, NARMAX, RiceDST, RDST).

To analyze the Timing Error, two events that had two minima during the time period under consideration were split in two: Event 1 had its first $\text{D}_{\text{st}}$ minimum at 10:00 UT on 29 Oct 2003 and the second minimum at 1:00 UT on 30 Oct 2003. The event was split at 14:00 UT on 29 Oct 2003 (shown as vertical line in Figure 4a). Event 2 has the first minimum at 2:00 UT on 15 Dec 2006 and the second at 09:00 UT. The split was done at 03:00 UT on 15 Dec 2006 (Figure 4b).

[52] In the following sections, we describe the results obtained with the skill scores. Rankings shown in plots described below were obtained for model settings that were run in at least three of the four events. This excludes 3_RCM, 4_RCM (both run for only one event), 4_RAMSCB and 5_RAMSCB (run for two events).

6.1. Correlation Coefficient and Prediction Efficiency

[53] We compute $CC$ and $PE$ using 1 minute USGS and 1 hour Kyoto $\text{D}_{\text{st}}$ observations and model results interpolated to 1 minute snapshots when using USGS data or averaged to the 1 hour cadence when using Kyoto data.

[54] Figure 5a, shows the ranking of all runs using the Correlation Coefficient ($CC$) based on comparison with 1 minute USGS $\text{D}_{\text{st}}$ data and Figure 5c shows the ranking from the comparison with Kyoto $\text{D}_{\text{st}}$ data. In Figure 5a, the specification models (shown in black) appear at the left of the plot. RiceDST suffered weak performance for two
One hour KYOTO $D_s$ data and $D_s$-specification model results. Kyoto $D_s$ is shown in black and the $D_s$-specification model results are shown in colored traces. Simulation runs are listed in the bottom section in Table 2. IRF96 is shown in purple, BFM in brown, NARMAX in blue, RiceDST in green and RDST in red. The first two events feature two minima of $D_s$ and are split in two for Timing Error metric analysis along the vertical lines shown in Figures 4a and 4b. In comparison with Figures 2 and 3, one may note the difference in the baseline between the Kyoto and the USGS $D_s$ index. This is especially apparent for the weakest event shown in Figures 2c and 3c.

events and fell outside of the range occupied by the other statistical models. Event 3 resulted in weak performance for most models as can be seen from the diamonds appearing far below the averages. A few magnetosphere models, BFM and RiceDST, do not perform well for event 1, shown as squares.

Several of the magnetosphere model runs (WINDMI, 7_SWMF and 8_SWMF, shown in red) and one ring current model (3_RCM, shown in blue) closely match the performance of the statistical models (shown in black), followed by the bulk of ring current models (all three RAM-SCB settings were run for three events and 2_RCM, shown in blue). On the right half of the plot, the remaining magnetosphere models (6_SWMF, 2_LFM-MIX, 2_CMIT, and the OPENGGCM runs) exhibit a wide variation of performance between the events with average scores near zero (no skill).

We also note that event 3 (diamonds) results in poor performance for nearly all models (many physics-based and all statistical models). Several models also show poor performance for event 1 (square well below the average for 1_BFM, 8_SWMF, 5_SWMF, 6_SWMF, 1_RiceDST and 4_OPENGGCM). Results for event 4 are always above average and mostly above average for event 2. The ranking is only slightly changed when comparing against Kyoto $D_s$ in Figure 5c.

Figure 5b shows how the models perform using the Prediction Efficiency $PE$ using USGS $D_s$ data and Figure 5d shows $PE$ results using Kyoto $D_s$ data. The ranking is completely different from the ranking derived from the $CC$ scores: Three of the RAM-SCB runs (1_RAMSCB, 3_RAMSCB, 5_RAMSCB) are followed by two SWMF runs (6_SWMF, 8_SWMF) then followed by 3_RCM, 1_NARMAX and 2_RCM. The center is dominated by magnetosphere models mixed with statistical models.

The Prediction Efficiency $PE$ takes into account the variance of the observed signal during an event in relation to the difference of observations and model results. In contrast to the Correlation Coefficient, $PE$ includes the effects of biases and the amplitude of the modeled signal in addition to the shape of the time series. Anti-correlated signals and signals with good correlation but incorrect amplitudes may result in negative $PE$ scores.

Between Figures 5b and 5d, we can see two differences in $PE$ between USGS and Kyoto $D_s$: The first difference is that the 1 hour averaging results in better $PE$ scores for all models. The spread of scores between the events for each model is much smaller. The second difference is that $PE$ scores derived from USGS $D_s$ in Figure 5b for event 3 are far below the average for almost all models. In Figures 5d, $PE$ scores derived from Kyoto $D_s$ for event 3 agree better with $PE$ scores from other events. This has the largest effect on the $D_s$-specification models that rank near the top of all models when averaged over all events. This change in the performance of the specification models can be explained by the fact that they were developed to match the Kyoto $D_s$ including its baseline. Scores for event 3 with its small $D_s$ amplitude are most sensitive to the baseline, which is different in USGS data compared to Kyoto data.
6.2. Model Yield

Figures 6a and 6c show the model runs sorted by Model Yield (\(YI\)). Low values are on the left and high values on the right. Best-scoring models (\(YI \sim 1\)) are near the right of each panel. Figure 6a shows the ranking when using USGS \(D_s\) data and Figures 6c shows the ranking when using Kyoto \(D_s\) data: The \(D_s\)-specification models all score between 0.5 and 1.3 with the RDST model being the closest to 1 on average and with the smallest spread between the events. Magnetosphere runs 7_SWMF and 8_SWMF are performing equally well. A few ring current models (1_RCM, 2_RAMSCB, 4_RAMSCB) perform well on average but with a considerably larger variance among the events. Magnetosphere model runs with the exception of 7_SWMF, 8_SWMF and the two OpenGGCM runs yield an average score below 1, indicating that the models only weakly reproduce the changes of \(D_s\) or that they do not see the signal at all. The models’ average \(YI\) values are very similar in the comparisons with USGS and Kyoto \(D_s\) and only a few models change places between the two panels. The model that changes position most is OpenGGCM, which experienced the largest short-term fluctuations. Averaging
Figure 6. Model ranking using Yield ($YI$), Log-Spectral Distance $M_s$ and Timing Error $\Delta T$. For $YI$ in Figures 6a and 6c (USGS and Kyoto $D_{st}$, respectively), the best performing models are near the right (nearest the score of $YI = 1$, shown as the dashed near the middle of the vertical range of each panel). Figure 6b shows the log-spectral distance $M_s$ based on USGS $D_{st}$ with best-performing models on the left. For the Timing Error $\Delta T$, based on Kyoto $D_{st}$, in Panel d), events 1 and 2 have been split and two values have been obtained. These values are indicated by the two squares with a diagonal line for event 1 and two triangles with a vertical and horizontal line for event 2. The best models (near $\Delta T = 0$) are on the left of the plot. Ideal scores ($M_s = 0$, $\Delta T = 0$) are shown as dashed lines near the bottom of the vertical ranges in both panels.

reduces the $YI$ values considerably. The spread between events for individual models is similar in Figures 6a and 6c.

6.3. Log-Spectral Distance and Timing Error

[61] Figure 6b shows the model runs sorted by Log-Spectral Distance $M_s$ with the best-scoring models (lowest values of $M_s$) on the left. Of the specification models, only BFM is included here since it produces output at the 1-minute cadence for a fair comparison in this skill score. The magnetospheric models 8 SWMF and 7 SWMF rank best together with the BFM model, featuring a low average and small variation between the events. The ring current model 2_RAMSCB matches the performance on average but Event 3 posed a challenge. 2_RAMSCB (as all the other RAM-SCB settings) was not run for Event 1.

[62] Figure 6d shows the model runs sorted by Timing Error $\Delta T$ with the best score (zero) on the left. To be acceptable, the Timing Error should be zero or 1 hour for events with a well-defined minimum of the $D_{st}$. The $D_{st}$ specification model (and 2_RAMSCB) in the left third of the plot performed best, predicting the $D_{st}$ minimum within 2 hours, except for the second section of event 2. Moderately successful models (WINDMI, 8_SWMF and 5_SWMF, 1_RAMSCB and 3_RAMSCB, 2_CMIT and 2_RCM in the center) predicted the minimum within 5 hours. Models on the right, third of Figure 6d show a very large variance between the events. Scores of six or larger indicate that the models did not predict the minimum at all. The modeled minimum is assumed at a random place anywhere in the time frame of the event. All magnetosphere models (except

*The models are listed in the order they are introduced in Table 2, starting with magnetosphere models, then ring current models, and, finally, $D_s$-specifications. Standard error values of NaN (Not-A-Number) appears where a model was only run for a single event.

WindMi), RCM, and RiceDST have runs that fall into this category for at least one event.

Table 3 summarizes the skill scores used for the rankings presented in this section (average over all events and standard deviation). All skill scores were computed for Kyoto $D_s$ values (1 hour intervals) and USGS $D_s$ (1 minute intervals). Some models were run for only a single event and “NaN” (Not-A-Number) appears as the standard deviation. For the plots and rankings in this chapter, PE values derived from Kyoto data as listed in Table 3 were not used.

6.4. Two-Dimensional Scores

A visual impression of the distribution of the different model classes in the multi-dimensional skill score space can be obtained by plotting each model run’s position with respect to two skill scores. In Figure 7, we present the locations of runs in $P-E$-space (left column) and $ΔT-Y$-space (right column). The top row shows results of magnetosphere model runs, the middle row the ring current model runs and the bottom row shows the $D_s$-specification models. Dashed lines in each panel illustrate the ideal scores of each of the two skill scores with the intersection denoting the ideal combined score. A run is identified by symbol size and color, events are identified by the different shapes of the symbols.

We note that the different types of models show distinct distribution patterns: Magnetosphere models fill a wide area in the $P-E$-space with most model runs with $PE > -6$ and $CC > 0$ (only 4 OpenGGCM and 2 LFM-MIX show one score outside that range). WindMi runs (green, dark green) are characterized by higher $CC$ values ($CC > 0.5$). WindMi runs are joined by runs of Swmf (7 SWMF, 8 SWMF, red) near the ideal score ($PE > 0$, $CC > 0.8$). In $ΔT-Y$ space, most model runs exhibit low Yield values $0.1 < Y < 0.9$. A few (mostly OpenGGCM
Figure 7. Model runs in 2-D skill score space. (a, c, e, left column) Prediction Efficiency (PE) and Correlation Coefficient (CC), with Figures 7a and 7c using USGS $D_{st}$ values and Figure 7e using KYOTO $D_{st}$ values. (b, d, f, right column) Timing Error ($\tau_{\text{min}}$) from minimum $D_{st}$ value and Model Yield ($YI$) based on Kyoto $D_{st}$. The Figures 7a and 7b, show magnetosphere models, Figures 7c and 7d, show ring current models, and Figures 7e and 7f, show $D_{st}$-specification models. Model runs are listed on the top right in each panel with a sample symbol for event 1 shown. The color scheme is the same as in Figure 2. Runs that share a color are distinguished by symbol size. Each model setting may be run for up to four events, symbolized by a square for event 1, a triangle pointing down for event 2, a diamond for event 3 and a triangle pointing up for event 4. Dashed lines in the plot (vertical for the X-axis score, horizontal for the Y-axis score) indicate perfect scores. Events 1 and 2 have been split to determine $\tau_{\text{min}}$.

Runs) have too large Yields (up to $YI = 3.25$). Scores below $YI = 1$ may be attributed to a weak dynamic response of MHD models due to inevitable damping, diffusion and the lack of inner-magnetospheric physics if a ring current model is not coupled into the MHD model of the magnetosphere. The Timing Errors vary widely (up to 18 hours, comparable to the entire length of a simulation, typically 24 hours). One might expect that runs that score low in $YI$ may also exhibit large $\Delta T$ values. This was not the case as we found both good and bad scores in $\Delta T$ regardless of the Yield score.

[67] SWMF runs are consistently below or near $YI = 1$, with the ones having coupled CRCM or RCM (7_SWMF and 8_SWMF, red) scoring close to or slightly above 1. Even runs with a good Yield (such as 7_SWMF and 8_SWMF) may score poorly in $\Delta T$ if they predicted the global minimum at the time when a smaller, temporary minimum was reached (such as in event 1). WINDMI runs, in general, represented the time history of $D_{st}$ well, resulting in good scores in terms of Timing Error ($\Delta T \leq 3$). Yields, however, were more varied than for runs of SWMF ($0.15 < YI < 1.6$). CMIT and LFM runs scores fairly in terms of Timing Error ($2 \leq \Delta T \leq 7$) and also fairly in terms of Yield ($0.3 \leq YI \leq 0.7$). OpenGGCM runs tend to over-estimate variability and often resulted in $YI > 1$. However, the time series of $D_{st}$ were seldom reproduced. We saw low correlations and minima that were reached at random times giving poor scores ($\Delta T$ up to 13 hours). Sometimes, model runs (e.g., 7_SWMF, 8_SWMF, and WINDMI runs) would continue to predict decreasing values of $D_{st}$ although the observation indicates a recovery (e.g., event 2 in Figure 2b).

[68] Ring current models populate a smaller area in PE-CC space ($PE > -2, CC > 0.2$) than the magnetosphere models. RAMSCB features higher scores ($CC > 0.6$). RCM run scores are in the middle ($0.3-0.9$). Best-performing
combined scores have been achieved with RAM-SCB, but several RCM runs come near the ideal score as well. In terms of $\Delta T$ and $Y$, ring current models show a smaller scatter in $\Delta T$ ($\leq 13$) than the magnetosphere models and a similar range in Yield ($0.1 < Y < 21.8$). All RAM-SCB runs and all RCM runs have $\Delta T \leq 5$. RAM-SCB $Y$ scores are below 1, except one for event 4 at $Y = 1.7$ and RCM $Y$ scores can reach values up to 1.8.

Most $D_{st}$ specification models do very well in PE-CC-space compared to first-principles models. All but one of the runs for events 1, 2 and 4 have $PE > 0.1$ and $CC > 0.7$. All models, however, score poorly for event 3 (diamonds scattered between $-1 < PE < 0$ and $0.3 < CC < 0.85$). The relatively weak $D_{st}$ minimum (−40) and the shape of the time series of $D_{st}$ for that event proved difficult to predict by all of the models. Many models showed a bias of up to 15 nT at the beginning of the time period shown in Figure 4, which severely impacted their $PE$ score.

In $\Delta T$-$Y$ space, all specification models are close to the ideal Yield and many show good to moderate Timing Errors ($\Delta T < 5$). Event 2 proved challenging, with $D_{st}$ fluctuating near the minimum for nearly 9 hours resulting in all models to score between 4 and 7 hours in $\Delta T$. RiceDST performed poorly for event 1 on all scores. It predicted the global minimum near the time of the weaker minimum seen early in the event time period but missed the larger minimum altogether.

7. Discussion

The large number of models were categorized into magnetosphere (MHD) models, ring current (kinetic) models and $D_{st}$-specification models: Magnetosphere models are coupled magnetosphere-ionosphere models that may include a ring current model component. Most magnetosphere models are—DMHD models with the exception of WINDMI, which describes the energy flow from solar wind into the magnetosphere, ring current and ionosphere in a low-dimensional manner. Ring current models are kinetic models of the drift physics in the inner magnetosphere that were either run in stand-alone mode driven by statistical plasma sheet, electric field and magnetic field models or were run coupled to magnetosphere MHD models. $D_{st}$-specification models run instantly off the solar wind data and (mostly) predict $D_{st}$ on a 1 hour cadence to replicate the Kyoto-$D_{st}$ index.

Five skill scores were used in the investigation:

Correlation Coefficient: In terms of Correlation Coefficient ($CC$), we found that specifications of $D_{st}$ performed best (led by 1_RDST, followed by 2_NARMAX 1_BFM and 1_NARMAX runs) with several coupled magnetosphere-ring-current-ionosphere models (all WINDMI runs, 7_SWMF and 8_SWMF) following not far behind. In the middle were stand-alone ring current models (all RAM-SCB runs and three RCM runs) and an older version of a coupled magnetosphere-ring-current-ionosphere model (5_SWMF). RiceDST fared worst among the specification models, scoring in the trailing third of all models, just ahead of magnetosphere-ionosphere models not containing a ring current component, i.e., the two OpenGGCM runs, 2_CMIT and the 2_LFM-MIX runs (listed not in order of performance).

Prediction Efficiency: If we look at Prediction Efficiency, which also takes into account model biases and the variance of the modeled signal, the ranking is considerably different. Prediction Efficiencies change when the model comparisons are made against the Kyoto $D_{st}$ instead of the USGS $D_{st}$ data. Event 3 yielded far worse model scores with USGS $D_{st}$ compared to Kyoto $D_{st}$, especially affecting the specification models. All models experience a larger variation of scores between the events when compared against USGS 1 minute data, reflecting the challenge faced by all models to specify the data on short time scales. Like CC scores, PE scores were worst for magnetosphere-ionosphere models that do not contain a ring-current component.

Model Yield: In terms of Yield ($Y$), best-scoring models are the versions of SWMF that have ring current models coupled into the magnetosphere (7_SWMF with CRCM, 8_SWMF with RCM), several RCM runs (1_RCM and 3_RCM, on average) and RAM-SCB runs (2_RAMSCB, 4_RAMSCB, on average) and 1_RDST. Specification models other than RDST show yields below unity as well as most magnetosphere magnetohydrodynamic models without coupled ring current models. OpenGGCM and WINDMI runs suffer from a very large variability in $Y$ between the events, often exceeding unity for some events while remaining far below unity for other events.

Log-Spectral Distance: The log-spectral distance was computed using USGS data and excluded most specification models because of their 1 hour output resolution. The one specification model (1_BFM), the two coupled magnetosphere-ring-current-ionosphere models (8_SWMF, 7_SWMF), and 2_RAMSCB did best. CMIT/LFM and OpenGGCM runs followed close behind. Most models in trailing positions (WINDMI, other RAMSCB, RCM and 4_SWMF) had large (poor) scores coming from the substorm event (event 3).

Timing Error: Timing errors were derived using the Kyoto $D_{st}$ and were measured in full hours. Events 1 and 2 had to be split to account for separate $D_{st}$ minima that occurred. Models that scored well in $CC$ or $PE$ did best here as well: Specification models are leading together with some of the stand-alone ring current models and the SWMF runs that include a ring current component. In event 3, 7_SWMF failed to follow the recovery of $D_{st}$ after the isolated substorm and thus scores a large error. WINDMI runs, as well as many of the ring current models, did not see the substorm at all.

In this study, we found that each skill score by itself is not a very reliable measure of model performance. We found that $D_{st}$-specification models performed very well for the stronger events, but failed in terms of Prediction Efficiency due to differences in the baseline (the Kyoto and USGS $D_{st}$ values at the start of the interval for event 3 differed by 8 nT). Prediction Efficiency is very sensitive to this type of bias for weak events. Another part of the difference between Correlation Coefficient and Prediction Efficiency can be explained by the Yield. Imperfect Yields paired with
good correlations result in worse performance in terms of Prediction Efficiency. The $D_a$-specification models consistently show $YI < 1$ and as a group show worse rankings in $PE$ than in $CC$. The Timing Error, together with the Model Yield and Correlation Coefficient adds another dimension to the analysis of model performance to reproduce a time series of an index value.

[76] To visualize the performance of groups of different models, we plotted scores for each run for the individual events in 2-D plots (one on $PE$-$CC$ space, the other in $\Delta T$-$YI$ space). We plotted the magnetosphere models, the ring current models and the $D_a$-specification models separately and found that the groups of models filled the skill score space quite differently. Magnetosphere model runs fill a large area in $PE$-$CC$ space ($PE > -11$, $CC > -0.15$). The scatter was also large in $\Delta T$-$YI$ space ($\Delta T \leq 12$, $0.1 < YI < 1.7$). Larger timing errors were encountered more often for lower-yielding model runs. Most ring current model runs were clustered much closer to the ideal $PE$ score ($PE > -2$, except for one run with $PE = -5.5$) with a smaller range in $CC$ ($CC < 0.2$). Ring current models showed a smaller scatter in Timing Error ($\Delta T \leq 5$ hours) and a little less in Yield ($YI < 1.8$). Most Yields were well below unity as was the case with magnetosphere runs. $D_a$ specification models were very close to perfect in Prediction Efficiency and Correlation Coefficient except for event 3 that challenged all the models. Timing errors were small to moderate ($\Delta T \leq 5$ hours, except for one run at 11 hours) and yields were closer to unity ($0.5 < YI < 1.4$) for all runs and events compared to the other model groups.

[80] No single model scores best in all the skill scores. The study included several sets of similar model settings: four SWMF, two OpenGGCM, two LFM (2 CMIT, 2_LFM-MIX), three WINMDI, five RAMSCB, four RCM, and two NARMAX runs. We found best-performing model settings for some models, while other model run sets did not show any preference for any one run:

[81] Magnetosphere Model Runs: Among the SWMF magnetosphere model runs, 8_SWMF (with CRCM) and 7_SWMF (with RCM) scored best, followed by 5_SWMF with an older implementation of the coupling of the magnetosphere MHD to the RCM model, and then 4_SWMF without any ring current model. Out of eight cases ($YI$, $CC$, $PE$, $M_e$ computed using USGS, and $YI$, $CC$, $PE$, $\Delta T$ computed using Kyoto $D_a$), 8_SWMF scores best six times and 7_SWMF two times. 5_SWMF is second once and 4_SWMF always scores lowest among the SWMF runs. The four SWMF runs do differ in terms of resolution near the Earth: 7_SWMF and 5_SWMF have a finer grid than 8_SWMF and 4_SWMF. The increased resolution does not seem to benefit a model run: 8_SWMF with 0.25$R_e$ resolution leads or performs similarly to 7_SWMF with 0.125$R_e$ resolution. Among the two runs with coupled RCM, 8_SWMF always scores better than 5_SWMF, although the latter has the finer resolution. The role of the grid resolution in the quality of the magnetosphere ring-current coupling needs to be investigated in a separate study.

[82] WINMDI results were mixed with 1_WINDMI (rectified solar wind driver) leading in four of the eight cases, and 2_WINDMI (Siscoe solar wind driver) and 3_WINDMI (Newell solar wind driver) leading in two other scores each. CMIT (the newer model version 2-1-5 with TIE-GCM ionosphere) scored practically identical to 2_LFM-MIX (model version 2.1-1). There was no clear preference among the OpenGGCM runs (2_OpenGGCM scored best in five out of eight cases).

[83] Ring Current Model Runs: None of the RAMSCB runs were executed for Event 1, indicating that solar wind magnetic fields and plasma velocities exceeded the valid range of the Volland-Stern and Weimer electric field models as well as the LANL-SOPA plasma sheet models. 4_RAMSCB and 5_RAMSCB were not run for events 1 and 2 due to their computational cost as they were coupled to the SWMF magnetosphere MHD model. Large values of $B_z$ in the solar wind during event 1 also exceeded the valid range of the statistical Tsyganenko-Mukai plasma sheet model driving 1_RCM. Large values of $V_z$ exceeded the range of the Borovsky et al. plasma sheet model driving 2_RCM. Special settings in runs 3_RCM and 4_RCM were introduced for this event. None of the RCM run settings performed for all events. The four events represented very different solar wind driving conditions and responses of the magnetosphere. Stand-alone ring current models depend on their drivers (statistical plasma sheet and field models) and several settings need to be run to have one match the observed behavior. A thorough assessment of the performance of the RCM drivers represented here is in preparation by S. Sazykin.

[84] Among ring current models, 2_RAMSCB ranked best among the RAM-SCB runs. The RAM-SCB runs driven by first-principles models (4_RAMSCB and 5_RAMSCB) were executed for only two events (3 and 4), which did not provide enough data for a valid comparison with all models based on all events. On average, 4_RAMSCB scored second for two metrics ($YI$, $\Delta T$) and fourth for $PE$. 5_RAMSCB scored last for $PE$ and $YI$ and first for $\Delta T$. All runs score very similarly in $CC$.

[85] $D_a$-specification Model Runs: Among the $D_a$-specification models, only the NARMAX model had multiple runs: 2_NARMAX outscored 1_NARMAX in $CC$ and $PE$ but 1_NARMAX leads in terms of $YI$ and $\Delta T$, favoring none.

[86] We had model runs that scored nearly perfectly in the timing of the minimum $D_a$ value, but performed poorly in terms of other scores such as Yield or Correlation Coefficient. Many model runs poorly estimated the time of the $D_a$ minimum. In event 1, several models predicted a single minimum early and then predicted a slow recovery while the observation shows a weak minimum that was followed by a stronger minimum several hours later. In this case, models may score well on the Yield, but poorly in Timing Error and fairly well in terms of Correlation Coefficient. In event 2, the time of the $D_a$ minimum was hard to predict since the $D_a$ fluctuated near the minimum value for an 8 hour period. Models that fail to predict a pronounced minimum usually have a large Timing Error (the minimum may be at any random time during the time intervals), a low Yield, poor Correlation Coefficient and Prediction Efficiency scores.
In general, the $D_{st}$ specification models perform best but some first-principles models come close for some events, especially during the stronger storms. The weakest event (event 3, the isolated-substorm event) poses a particular challenge for the physics-based models. The $D_{st}$ specification models struggle to get the baseline right even if they managed to predict the substorm during the event. Since the USGS $D_{st}$ features a baseline that is different from the Kyoto $D_{st}$, the specification models that were developed to match the Kyoto $D_{st}$ do much worse when compared to USGS $D_{st}$ data. RDST scores best since it is a real-time implementation of the $D_{st}$ index using magnetometer data from a set of four magnetometers that is similar to the set used for the Kyoto $D_{st}$ index (RDST uses Guam instead of Kyoto). Unlike the first-principles models and the other specification models, RDST cannot be run using solar wind measurements to obtain a prediction ahead of actual observations on the ground.

The results of this challenge provide a baseline for future validation studies using new models and improved models. Model outputs used in this study together with the observation data are available on the CCMC web site (http://ccmc.gsfc.nasa.gov under “Magnetic and Validation” and then “GEM Challenge”) for use by the space science community. Skill scores as presented in this paper can be obtained through the online visualization tool as well.

Acknowledgments. Hourly $D_{st}$ data were obtained from the World Data Center for Geomagnetism, Kyoto, Japan and 1-minute data were obtained from the United States Geological Survey (USGS). Both index values include magnetic data from the following stations: KAK: Kakioka Magnetic Observatory, Japan Meteorological Agency, Japan, HON: Honolulu and San Juan magnetic observatories, USGS, HER: Hermanus Magnetic Observatory, South African National Space Agency (SANSA). Solar wind input data for the models (magnetic field and plasma parameters) were obtained from OMNI (http://omniweb.gsfc.nasa.gov) and CDAweb (cdaweb.gsfc.nasa.gov) databases. This work was supported by the Center for Integrated Space Weather Modeling, which is funded by the NSF. Fullerton-Rowell, T., D. Rees, S. Quegan, R. J. Moffett, M. V. Codrescu, and G. H. Millward (1996), A coupled thermosphere-ionosphere model (CTIM), in STEP Report, edited by R. W. Schunk, p. 217, Scientific Communications on Solar Terrestrial Physics, Boulder, Colorado.
